Functional diversity in fish assemblages of the Tropical Eastern Pacific Ocean: A review of two decades of progress in the functional diversity approach

Diversidad funcional en el ensamblaje de la ictiofauna del Océano Pacífico Oriental Tropical: Una revisión de dos décadas en su enfoque

ABSTRACT

Background. One of the most relevant topics in ecology and evolution is understanding the relationship between biological and functional diversity at the ecosystem level; both important in the evolutionary processes and the structuring of complex communities. Goals. In this essay, the explanatory hypotheses focused on global patterns of the distribution of species are described along with selected hypotheses relating species richness/biodiversity to ecosystem function, and the differentiation of the terms guild and functional group are discussed. Methods. Both biodiversity and functional diversity are key in the evolutionary processes and the structuring of complex communities and thus examples of functional equivalence of convergent evolution derivatives are presented in terms of the form and ecological habits of fishes of the Tropical Eastern Pacific Ocean. Finally, the importance of redundancy in ecosystem functioning is examined as well as the impact of environmental disturbances on ecosystem function. Results. In general, systems with low species richness and redundancy within functional groups are more vulnerable to disturbances. However, despite the extensive effort to understand the relationship between species richness/biodiversity and ecosystem functioning, there is no consensus on the effect of species loss on the functioning of the ecosystem. Some hypothesize that each species is unique and plays a unique role in the ecosystem whereas alternate hypotheses indicate that species overlap in function supporting sustainability at the ecosystem level, such that the removal of one species function may be replaced by another. Conclusions. The most widely accepted concept is that a greater number of species increases the efficiency in the use of resources and also provides resilience against environmental changes or impacts through functional redundancy.

Keywords: biological diversity, ecological redundancy, evolutionary convergence, functional equivalence

RESUMEN

Antecedentes. Un tema relevante en ecología y evolución es la relación entre la diversidad biológica y la funcional a nivel del ecosistema; ambas importantes en los procesos evolutivos y la estructuración de comunidades complejas. Objetivos. Discutir hipótesis explicativas centradas en los patrones globales de la distribución de las especies junto con hipótesis seleccionadas que relacionen la riqueza y la biodiversidad de especies con la función del ecosistema. Diferenciar los términos de gremio y grupo funcional. Metodología. Presentar ejemplos de equivalencia funcional de los derivados de evolución convergente en términos de la forma y los hábitos ecológicos de los peces del océano Pacífico oriental tropical. Examinar la importancia de la redundancia en el funcionamiento de los ecosistemas, así como el impacto de las perturbaciones ambientales en la función del ecosistema. Resultados. En general, los sistemas con baja riqueza de especies y redundancia dentro de grupos funcionales son más vulnerables a las perturbaciones. Sin embargo, a pesar del extenso esfuerzo por comprender la relación entre la riqueza de especies/biodiversidad y el funcionamiento del ecosistema, se encontró que no existe consenso sobre el efecto de la pérdida de especies en el...
INTRODUCTION

Biological classification (taxonomy) aims to simplify and order the diversity of life into coherent units called taxa; however, there is currently no consensus among taxonomists concerning which classification scheme to use (Ruggiero et al., 2015). Simply, taxonomy integrates diverse, character-based data in a phylogenetic framework, which allows the use of this knowledge of shared biological properties of taxa but there is still strong debate over their accounting for evolutionary divergence or information content other than the branching pattern (Stuessy & Hoerandl, 2014). In contrast to taxonomy and phylogeny approaches to Earths biodiversity, a central issue in population and community ecology is species’ geographical distribution and range size, which are important components needed for a better understanding of biodiversity. Generally, studies have focused on two different aspects: (1) patterns in species’ range size distributions (Gaston, 1996; MacPherson, 2003); and (2) the effect of latitude on species’ range sizes, e.g. Rapoport’s rule (Stevens, 1989; 1996).

However, in contrast to earlier research on mechanisms driving known biodiversity patterns (Winemiller et al., 2015; Pianka et al., 2017), recent work highlights that evolution works on ecological similarities (redundancy) and differences (complementarity) of individuals and not on the number of species (Cadotte et al., 2013). A number of early studies that simultaneously examined aspects of species biodiversity and functional diversity (reviewed in Tilman et al., 1997) have shown that species biodiversity is an important indicator of ecosystem functioning but functional diversity and species composition together are most important in grassland ecosystems. Functional diversity (trait-based) is generally defined as “morpho-physio-phenological traits which impact fitness indirectly via their effects on growth, reproduction, and survival, the three components of individual performance” (Viole et al., 2007). There is also evidence that functional traits strongly link to species composition and shifts in ecosystem processes (Villéger et al., 2010) and that the choice of functional traits is key to quantifying functional diversity and its use to examine anthropogenic modifications of ecosystems. This relationship is strong when many species have unique functional traits that are important in ecosystem functioning, whereas if many species have similar characteristics (redundancy), the relationship between species biodiversity and functional diversity is weak.

Natural or human-induced environmental modifications (e.g., fishing, climate change, habitat fragmentation) have had drastic impacts on habitats and species and thus biodiversity and ecosystem function worldwide (Costanza et al., 1997; Vitousek et al., 1997; Lotze et al., 2006; Halpern et al., 2008). These impacts are generally focused on habitat modification or loss as it relates to species loss and biodiversity reduction since it has long been postulated that habitat is the ‘template for ecosystem strategies’ (Southwood, 1977; Ferraro & Cole, 2010; Ferraro, 2013) and that habitat provides the organizing structure for ecosystem functionality. However, there are generally two approaches to assessing local and regional community assembly relative to diversity and ecosystem function: 1) taxonomic (phylogenetic); and 2) functional (trait-based) (Cadotte et al., 2013; Winemiller et al., 2015; Pianka et al., 2017).

The traditional approach is to examine changes by using species richness/biodiversity metrics but more recently a growing literature on functional diversity and its importance in better understanding ecosystem function (Viole et al., 2007; Villéger et al., 2010; Parravicini et al., 2014) is emerging, and, in particular, relative to species invasions and habitat degradation, and fishing pressure (Pecuchet et al., 2017; Silva-Junior et al., 2017; Villéger et al., 2017). For example, it has been shown in coral reef fish communities that functional diversity is lower than taxonomic diversity because of redundancy (Villéger et al., 2012, 2013; Mouillot et al., 2014) which suggests that one cannot use taxonomic diversity to predict changes in functional diversity nor can one use taxonomic diversity alone to assess habitat degradation and subsequent ecosystem functional capacity relative to stable and sustainable ecosystems (Villéger et al., 2014; Loiseau & Gaertner, 2015; Pecuchet et al., 2017; Silva-Junior et al., 2017).

The study of functional traits important to the community ecology and, by extension, ecosystem function has been most noticeable in plant communities worldwide with fewer examples in other taxa, including fishes and avifauna (Villéger et al., 2017). As a result of our empirical perception, we tend to assign a key role to a relatively small number of generally abundant and larger species, considering that their conservation is enough to maintain ecosystem processes and thus services. However, it was found that rare or unique species with the highest risk of extinction have, in some cases, a quantifiably important impact toward maintaining the functioning of the ecosystem, acting as key species (Lyons et al., 2005; Mouillot et al., 2013; Friedman et al., 2016; Escobar-Toledo et al., 2017).

Recent examination of freshwater, estuarine and marine fishes has illustrated the value of examining these communities based on functional traits in order to address pressing ecological issues associated with climate change, overfishing, invasive species, and habitat loss or alterations (Mouillot et al., 2014; Parravicini et al., 2014; Villéger et al., 2014; Chuang & Peterson, 2016; Pecuchet et al., 2016, 2017; Rodrigues-Filho et al., 2017; Silva-Junior et al., 2017).

With this essay, we aim to (1) summarize patterns of fish species richness/biodiversity and distribution in the Tropical Eastern Pacific Ocean (TEP), (2) provide a selective review of hypotheses relating fish species richness/biodiversityfunctional diversity to ecosystem function, and (3) review the importance of redundancy in ecosystem function and the impact of environmental disturbances. This essay will focus on marine fishes of the TEP but may provide examples from freshwater and estuarine fishes, and other vertebrate groups to illustrate a point.
MARINE FAUNAS TROPICAL EASTERN PACIFIC

The shallow, warm-water marine faunas of the world are traditionally divided into the Indo-West Pacific, Eastern Pacific, and western and eastern Atlantic regions (Ekman, 1953; Briggs, 1974). The Isthmus of Panama was established as one of the greatest natural events of the Cenozoic, driving profound biotic transformations on land and in the oceans, so faunas on the east and west sides are closely related and sister species are common (O’Dea et al., 2016). Furthermore, the TEP is divided from the rest of the Pacific by a wide expanse of deep ocean, with very few islands, coupled with cold water masses flowing along west coasts of both North and South America towards the equator. This is not a complete barrier to shallow-water invertebrate dispersal, but rather is a filter, allowing only those larvae with an exceptionally long life to be transported from the central tropical Pacific (Scheltema, 1988).

There is a substantial variation in species composition from north to south through the TEP region, but boundaries among biogeographical provinces are not always well defined. For example, mainly on ichthyological evidence, Briggs (1974) define four main provinces (Fig. 1), and places a boundary in the Gulf of Tehuantepec to separate the Mexicana province (Sinaloa to Oaxaca, on the coast of Mexico) and the Panamic province (Nicaragua to Ecuador, including Cocos and Malpelo). The Revillagigedo Islands was considered as part of the offshore Ocean Island province. However, the northern boundary of the Panamic province is debatable, the southern boundary is clearly defined by the cold Peruvian Current diverting offshore around Punta Aguja, Peru. Briggs (1974) set the northern boundary of the Mexican province in the Gulf of California and on Baja California at about 23°N. The Galapagos Islands are treated as a separate faunistic region and included in the offshore Ocean Island province along with the Revillagigedo and Clipperton Islands. The province of Cortez (southern Baja and the central Gulf of California) is isolated from its counterpart in the Mexican province by the Gap of Sinaloa, a band of 370 km of sandy and muddy shoreline extending between Topolobampo and Mazatlan, Mexico, whereas the Mexican province is separated from its counterpart in the Panamic province by the gap of Central America, a large 1,000 km section of coastline sand between the Gulf of Tehuantepec (south of Mexico) and El Salvador (Hastings, 2000).

Biogeographically, the TEP is fascinating in several respects. Its marine shore biota is most similar to that of the tropical western Atlantic, but, as a result of the independent evolution of their faunas in very different environments over the past 3.5 million years, the two regions share relatively few fish species (Rosenblatt, 1967; Castellanos-Galindo et al., 2013). The TEP includes five oceanic islands or archipelagos whose fish faunas are relatively well known (McCosker & Rosenblatt, 1975; Robertson & Allen, 1996; Grove & Lavenberg, 1997; Garrison, 2000; Galland et al., 2017). These islands harbor subsets of the mainland fauna, a significant number of insular endemics, and numerous species that also occur on the western side of the east Pacific barrier (Leis, 1984). The geographic isolation of the TEP has resulted in its having the highest level of regional endemism among shore fishes of any comparably sized region in the world. About 85 percent of its fishes are found nowhere else, although many of them regularly or periodically cross the thermal barrier to the north and are found in California (e.g., during El Niño events; Lea & Rosenblatt, 2000). Although less well documented, a similar periodic transgression of the southern terminal barrier presumably also occurs.

Many TEP fish species have wide distributions within the region. Others have more limited distributions, with the Panamic province and the Cortez province serving as centers of regional endemism (Fig. 1). Precise distributions of many species of fishes between these provinces, along with the coast of southern Mexico southward to Honduras, are not well documented. Some species, particularly small, benthic reef fishes, support the recognition of a third, Mexicana province located between the Cortez and Panamic province (Hastings, 2000), as suggested by several studies on the systematics of coastal fishes (e.g., Hubbs, 1952; Briggs, 1955; Springer 1959; Stephens, 1963).

**SPECIES RICHNESS / BIODIVERSITY AND DISTRIBUTION PATTERNS OF THE TEP FISHES**

Species richness/biodiversity is distributed irregularly among ecosystems across biomes. For example, there are 34 phyla alive in the marine environment, 17 in freshwater, and only 15 on land (Briggs, 1994; Mora et al., 2011). The contrast is higher when considering only animals, as there are 32 marine phyla and only 12 terrestrial fauna (Benton, 2001). However, although the ocean has the greatest wealth of phyla and it is about 300 times larger than the Earth’s terrestrial environment, species richness/biodiversity of the terrestrial realm is 25 times greater than the one found in the marine environment (Briggs, 1994; Mora et al., 2011). This difference in species richness/biodiversity is probably caused by three key conditions (Benton, 2001). First, land offers more endemism opportunities because of the effect of geographic isolation and independent evolution; marine environment barriers are not as efficient at reducing the possibility of endemism and diversification (e.g., soft barriers: Cowman & Bellwood, 2013). Second, terrestrial habitats are more diverse and heterogeneous, with large fluctuations in temperature and humidity throughout the day both seasonally and latitudinally; the physical marine environment is more stable compared to land. Third, the size of primary producer’s plays an important role as marine primary producers are mostly unicellular organisms that serve as food source for benthic and pelagic animals, but are unable to provide important habitat for other species of animals and plants like in terrestrial systems (Briggs, 1994; Mora et al., 2011).

Fishes worldwide consist of about 33,395 known species (Eschmeyer & Fong, 2013). They have very diverse latitudinal, longitudinal, and bathymetric distributions and very complex morphological, biological, and behavioral characteristics such that it is possible that both allopatric and non-allopatric speciation processes are involved in the formation of this biodiversity. How disjunct distributions (e.g., distributions composed of multiple geographically discrete and widely spaced populations) arise is an interesting question in biogeography and has long been subject of the dispersalist–vicariance debate (Cowman & Bellwood, 2013; Cowman, 2014). Dispersalist theories emphasize the importance of species traits and dispersal in explaining the occurrence of highly isolated populations, whereas vicariant theories invoke landscape evolution and fragmentation of a species’ ancestral range as the principal drivers of these biotic patterns. Species with geographically disjunct ranges are important for understanding the factors controlling species’ distributions, population connectivity, and the process of allopatric speciation (Ronquist, 1997; Cowen & Sponaugle, 2009; Cowman, 2014). In both cases, allopatric speciation can take place if the gap in a species’ range sufficiently limits gene flow (Crisp et al., 2010).

In the Mexican Pacific Ocean, two geological events have played a key role in the formation of the current fish fauna – the formation of the Gulf of California and the rise of the Isthmus of Panama (Jacobs et al., 2004). The formation of the Gulf of California dates about 5-8 mya during the Pliocene-late Miocene (De la Cruz-Agüero, 2000). The geological formation of Baja California divided a group of fish species that are disjunct populations on the Pacific coast and in the northern Gulf of California (Table 1); these eleven species represent an interesting case for studies of incipient speciation (Bernardi et al., 2003). The origin of these species from Magdalena-Almejas Bay and San Ignacio Lagoon is explained by the existence of interpeninsular Pleistocene-Holocene channels (0.115 - 2.6 mya) on sandy plains that connected the Pacific with the Gulf of California.

The geological development and endemism of species of tropical lineage support this hypothesis (Castro-Aguirre et al., 1995, 2005; De la Cruz-Agüero, 2000). In fact, most of the disjunct species of the Pacific and Gulf of California (Table 2) show few morphological and color differences, but in some cases divergence has been detected, as in members of the genus Leuresthes, Gillichthys, Girella, and Hypsoblennius (Crabtree, 1983; Orton & Buth, 1984; Huang & Bernardi, 2001; Bernardi, 2014). Bernardi et al. (2003) analyzed 12 species with disjunct populations and found that eight species had strong genetic differences between populations of the Gulf of California and the Pacific and four of them are in the process of incipient speciation, indicating that the genetic separation of populations (considered as the first step towards speciation) is very commonly responsible for the creation of new ge- nicate species.

In the TEP, families that experienced wide speciation patterns are Gobiidae (111 species), Sciaenidae (82 species), Serranidae (56 species), Labrisomidae (48 species), Gobiidae (43 species), Ophichthidae (41 species), Haemulidae (37 species), Labridae (36 species), Carangidae (35 species), Channidae (34 species), and Muraenidae (33 species). A number of these species groups can be partitioned into habitat-based subcategories like soft-bottom environments, coastal pelagic environments, estuarine, coastal lagoons, coastal pelagic zones, coral reef and rocky intertidal habitats where redundancy is higher, and subtidal habitats (Table 3). Another remarkable example of adaptive ra-
diation in the TEP is the moray eels of the genus *Gymnophiona*, with 11 indigenous species; some species inhabit subtidal reefs (*G. angusticeps* (Hildebrand & Barton, 1949), *G. castaneus* (Jordan & Gilbert, 1883), *G. davi (Günther, 1870), G. mordax* (Ayres, 1859), *G. panamensis* (Steindachner, 1876), *G. porphyreus* (Guichenot, 1848), and *G. serratidens* (Hildebrand & Barton, 1949)), and other soft bottoms (*G. equatorialis* (Hildebrand, 1946), *G. eurygnathus* Böhlke, 2001, *G. phalaris* Bussing, 1998, and *G. verrilli* (Jordan & Gilbert, 1883)). This genus has been enriched with the addition of species of Indo-Pacific or trans-Pacific affinity (*G. boroensis* Bleeker, 1857), *G. flavimarginatus* (Rüppell, 1830), *G. javanicus* (Bleeker, 1859), *G. meleagris* (Bleeker, 1859), *G. pictus* (Shaw & Nodder, 1795) and *G. undulates* (Lacepède, 1803), currently consisting of 17 species in total for TEP (Table 3).

Speciation events and the great topographic and bathymetric biodiversity have turned the Gulf of California into one of the most diverse regions of the TEP with about 875 species of fish, 92 of which are endemic (Thomson et al., 2004). This is regarded as a center of origin along with the Central America landscape (Mora & Robertson, 2003).

According with O’Dea et al. (2016), the formation of the Isthmus of Panama resulted in the absence of further gene flow between shallow marine animal populations after 3.2 million years (mid-Pliocene) by the interrupted the communication between the Pacific and Atlantic and particularly causing the effective isolation of fish populations, resulting in the formation of new species as well as the disappearance of others (Castro-Aguirre et al., 1995).

It is hypothesized that the presence of a marine Pleistocene gap in the area of Panama (1.8-2 mya), initiated the divergence of some transisthmian species of the genus *Anisotremus* (Tavera-Vargas, 2006). While 85% of the coastal fish fauna of the TEP is derived from taxa present before the rising of the Isthmus of Panama, the low percentage of common species in the two regions of the American continent (> 100 sister species, pairs or transisthmian; see Table 4) is the result of independent evolution of their faunas in very different environments (Rosenblatt, 1967; Robertson et al., 2004; Aguilar-Medrano, 2018). In some genera, the sister species have been separated taxonomically by minor morphological differences or genetic differences, such as the Pacific machete and Atlantic ladyfish (*Elops affinis* Regan 1909 - *E. saurus* Linnaeus, 1766), Pacific sleeper and bigmouth sleeper (*Gobiosoma maculatus* Gunther, 1859 – *G. doritor* Lacepede, 1800), the Pacific fat sleeper and fat sleeper (*Dormitator latifrons* (Richardson, 1844) - *D. maculatus* (Bloch, 1792)), Atlantic and Pacific spadefish (*Chaetodipterus faber* Broussonet, 1782) - *C. zonatus* (Steindachner, 1876), the Panamic banded benny and the red-lip benny (*Ophioblennius steindachneri* Jordan & Evermann, 1898 - *O. maclurei* (Silverste, 1915)). For the latter, a new species (O. *clippertonensis* Springer, 1962) has been recognized for Clipperton Atoll, a small isolated island at the western edge of the TEP (Allen & Robertson, 1997). In contrast, for some, the separation into two species is not possible or even questionable including the nurse shark *Ginglymostoma cirratum* (Bonnaterre, 1788), the lemon shark *Negaprion brevirostris*, the leatherjacket *Oligopistis saurus* (Poey,1868) the yellowfin mojarra *Gerres cinereus* (Walbaum, 1792) and the fringed flounder *Elops crosstus* Jordan & Gilbert 1882; these are remarkably similar in external morphology, but also in their behavior and ecology (Castro-Aguirre et al., 1995; Thomson et al., 2000).

</table>
Finally, tropical trans-Pacific fishes occur on both sides of the world’s largest deep-water barrier to the migration of marine shore organisms, the 4,000km to 7,000km-wide Eastern Pacific Barrier. They include 64 epipelagic oceanic species and 126 species of shore fishes known from both the TEP and the central and West Pacific. However, although trans-Pacific species are characterized by long larval stages, surprisingly, species with appropriate characteristics have not yet managed to colonize the TEP. While the region has a poor fauna, indigenous species are adapted to a very dynamic ocean environment with wide temperature fluctuations and salinity, heavy sediment discharges, reduced tidal ranges, many areas of upwelling, diverse estuarine-lagoon systems, a very narrow continental shelf, few islands and coral reef formations, extensive oxygen minimum layer, and especially the El Niño Southern Oscillation (Boschi, 2000; Glynn & Ault, 2000; Hastings, 2000; Lea & Rosenblatt, 2000; Robertson & Cramer, 2009; Aguilar-Medrano, 2007; Cadotte et al., 2013; Lefebvre et al., et al., 2015).

The latter two phenomena are probably intolerant conditions for alien species. Fish migrations of the TEP to the western Pacific (Hawaii and the Marquesas islands) are also known but in a smaller proportion (1:3; Robertson et al., 2004) and are characteristic of a high number of pelagic species or species associated with floating objects (Table 5). While trans-Pacific species contribute to an increase in species richness/biodiversity of the TEP, these species have different ecological characteristics compared to the local fauna, except in a few cases such as the genera Acanthurus and Ctenochaetus, and the two species of the genus Arthron. Despite these, there is no evidence of the invaders having biological or ecological characteristics that offer adaptive capabilities that may provide an advantage over members of the native fauna (Robertson et al., 2004).

SELECTED REVIEW OF RICHNESS / BIODIVERSITY HYPOTHESES AND ECOSYSTEM FUNCTION

Species richness depends solely on the number of species and thus the speciation processes whereas biodiversity depends on the abundance of each species in the ecosystem (Willig & Presley, 2017). Overall, there are about 50 hypotheses relating biodiversity to ecosystem function through simple hypothetical relationships that generally do not exemplify the true complexity of relationships in ecosystems (Naeem, 1998; Naeem et al., 2002; Thibaut & Connolly, 2012). All of these studies use sets of traits (morphological, physiological, phenological, ecological and biochemistry convergence, or similar trophic characteristics; Viole et al., 2007; Cadotte et al., 2013; Laureto et al., 2015; Villéger et al., 2017) to separate and enumerate species phylogenetically or functionally; these traits may link phylogenetic lineages and ecological processes in ecological and evolutionary time (Willig & Presley, 2017; Floeter et al., 2018).

Collectively, a functional trait is defined as one that can be measured in an organism and which is related to an effect on one or more ecological processes or a response to one or more environmental variables (Naeem & Li, 1997; Tilman, 2001; Diaz et al., 2007; Martín-López et al., 2007; Cadotte et al., 2013; Winemiller et al., 2015). This strategy used to represent the relationship between biodiversity and ecosystem function is a useful approach to simplify complex ecosystems based on a set of traits into units that facilitate comparative study among communities and are a low-resolution proxy to predict changes in the ecosystem. These traits can be compared directly or through calculation of functional diversity (e.g., Winemiller et al., 2015; Villéger et al., 2017) that can further our understanding of the mechanisms and processes shaping patterns of biodiversity. Regardless of definitions, the functioning of ecosystems is carried out by the joint action of physical processes and natural attributes (solar radiation, evaporation, rainfall, currents, tides, etc.), the activities of the species (nitrogen fixation, feeding, breeding, growth, competition, migration, waste excretion, etc.), and the effects their activities have on the physical and chemical conditions of their environment. Thus, the function of an ecosystem is not singularly determined by the phylogenetic biodiversity of biota (Floeter et al., 2018), but the functional traits of individuals, the distribution and abundance of these individuals, and their biological activity (Naeem & Wright, 2003; Viole et al., 2007; Cadotte et al., 2013; Diaz et al., 2013; Laureto et al., 2015; Villéger et al., 2017).

In recent years, the concept of functional groups has gained considerable popularity, particularly in plant ecology. Unlike the phylogenetic classifications, the approach is based on groups of functional traits that are ecologically significant and provide flexible classifications (Diaz et al., 2002; Villéger et al., 2017; Viole et al., 2007). Many of these ideas stem from Southwood (1977) who presented a view that habitat features provide the template for recurring properties of biotic communities and that habitats could be viewed as ecological periodic tables organizing communities. In fact, Lopez de Casenave (2001) indicates that the functional groups could represent the basic building blocks of communities and become the standard currency of the ecologists in their efforts to understand community relations. The forerunner that considered organismal traits in the classification of plants of ancient Greece into trees, shrubs and herbs was Theophrastus (300 BC; Diaz et al., 2002). In animals, Root (1967) was the first to employ classifications based on bird feeding strategies; these were called “guilds” and defined as a group of species that exploit a basic common resource in a similar way. Guilds or functional groups are comprised by generalist and opportunistic species with ambiguous boundaries that may in some cases be arbitrary (Root, 2001).

Pianka (1980) characterized guilds as arenas of intense interspecific competition with strong interactions, but weak interactions with the rest of their community. In contrast, Silvestre et al. (2003) indicates species belonging to a functional group would be those that exploited the resources within the n-dimensional niche in different ways, with a preference for certain portions of the food supply, differences in spatial occupation, or are active during different periods of the day. Furthermore, in tropical environments the effects of competition within functional groups appear minimized by the provision of non-limiting resources and the plasticity of behavioral strategies adopted by each species, avoiding agonistic encounters.

Some authors mistakenly use guild as a synonym of functional group. However, while functional groups simultaneously employ many traits related to the role of the species in the ecosystem, guilds are only based on the classification of a particular attribute (e.g., feeding, reproduction, etc.). Elton (1927) was one of the first to use the term niche in the sense of the “functional state of the organism within its community” and defined the niche as “the basic function of an organism in the community because of relationships with food and their enemies.” Subsequently, Root (2001) proposed to replace the Eltonian niche with “guild”. This change produced contradictions that occur when several
similar species are said to occupy the same niche; niche as a category is supposed to be a property of individual species (Blonder et al., 2014). Therefore, species exploit niches while guilds exploit niche corners (Root, 2001). In contrast, the more ecological traits of species (Winemiller et al., 2015) are employed to form functional groups, the closer we come to the definition of the niche; the fewer variables we have in the grouping of species, the closer we will approach the definition of guild (Root, 1967). Thus, Hutchinson (1957) suggested that niche could be viewed as the n-dimensional hypervolume within which the environment allows the individual or the species to survive indefinitively. Hutchinson also differentiated the maximum fundamental niche: “the hypervolume inhabited abstractly when the species is not restricted by competition or other limiting biotic interactions, and the realized (true) niche: the smallest hypervolume occupied” under specific biotic constraints (Odum & Barrett, 2006; Blonder et al., 2014; Pianka et al., 2017).

Finally, the guild approach has been developed emphasizing different life-history traits such that there is now a need to review the use of guild. The wide use of the guild approach has involved increasing overlap and/or confusion between different studies, which therefore increases the need for standardization while at the same time providing the opportunity to reconsider the types of guilds and their use worldwide. In fact, this term has lost its accuracy since its introduction, and has acquired a variety of meanings, ranging from functional analogs, ecological species, community guild, structural guild, functional guild, ecological species group, functional group, functional type, and many more (see Lopez de Casenave, 2001 for a review).

Until 2010, more than 90% of the studies using functional classifications were focused on terrestrial ecosystems. Of these, about 45% were plants, over 40% derived from experimental studies, and more than 30% were focused on the lifestyle of the species (Naeem & Wright 2003; Blaum et al., 2011). In plants, two main approaches are used to form functional groups on the basis of environmentally significant traits (Diaz et al., 2002), which can be generalized for animal studies (Barnett et al., 2007). The a priori strategy based on a single character or a very small number of traits to define different groups. The definition of groups is required prior to the study in question (subjective classification, Jaksic, 1981; Terborgh & Robinson, 1986; Blondel, 2003; Naeem & Wright, 2003) and a posteriori method, which is based on the collection of information on a number of traits and the subsequent identification of functional groups from the simultaneous consideration of all these traits through multivariate statistics (Winemiller et al., 2015; Pianka et al., 2017). Typically, the functional groups and the most relevant traits are not defined before starting the study, but arise as a result of the study (objective classification; Hawkins & MacMahon, 1989; Simberloff & Dayan, 1991; Naeem & Wright, 2003; Winemiller et al., 2015; Pianka et al., 2017) regarding the environment or particular influence on ecosystem processes responses (Hooper et al., 2002).

The type and number of traits used in functional classifications vary according to the scale of analysis and research objectives. Clearly, identifying key ecological traits involved in the processes of ecosystems is a major challenge to understand how species biodiversity affects ecosystem function. In general, most species within a specific ecosystem have similar environmental tolerances and occupy similar niches (Elliot et al., 2007). Naeem & Wright (2003) indicated that the relationship between taxonomic biodiversity and functional diversity is sensitive to the character response and effect employed, function being assessed, the degree of redundancy and uniqueness of species, trophic interactions and trophic structure, and the biogeographic factors controlling species composition, distribution and abundance. Thus, if rare species are redundant, then ecosystem function may be insensitive to the loss of some of them, while the opposite happens if the rare species is unique. Redundancy and uniqueness may vary depending on the trait measured and effect response employed (Tilman et al., 1997; Petchey & Gaston, 2006; Villéger et al., 2010, 2014). In fish, morphology plays an important role in determining the type of prey consumed and morphological variation can lead to changes in foraging ability and a subsequently differential exploitation of food resources (Karpouzi & Stergiou, 2003; Cruz-Escalona et al., 2005).

For example, the caudal fin generates propulsion and is important in maintaining swimming speed over long sustainable periods and also provides speed and acceleration (Fulton, 2007). However, the existence of species with different requirements and different evolutionary histories hinders determining a standard functional classification scheme to define functional groups. Some traits may be expressed by one or a few species in an association, whereas, others may have many unique traits, but it should be noted that some functional traits differ ontogenetically within a species (Villà, 1998; Naeem & Wright, 2003; Winemiller et al., 2015).

This variation challenges the classifications in functional a priori groups. For example, the classic fish example is the pinfish Lagodon rhomboides (Linnaeus, 1766) that presents an orderly progression of changes in trophic preferences (Livingston, 2002). One-year-old young recruits (< 20 mm standard length, SL) are primarily planktivorous, but as they grow (21-33 mm SL) they have a gradual transition to benthic carnivores, feeding on amphipods, mysids, and harpacticoid copepods, and at ~60 mm SL, they prefer amphipods, shrimp, algae and detritus. Fish between 61-120 mm SL eat crabs, shrimps and bivalve mussels and once they exceed 120 mm SL they generally feed on seagrass, being practically herbivorous. The transition from one feeding stage to the next is gradual, but, in general, related to stages of growth associated with ontogenetic changes in morphology (dimension of the mouth, teeth, and size of the stomach) and body shape (Livingston, 2002).

Some authors suggest that there is a degree of predictability in the process of convergence. If there are similar resources in two geographically isolated locations, it is possible that a group of similar species may eventually converge despite phylegetic differences (Schluter & Ricklefs, 1993; Winemiller et al., 2015; Pianka et al., 2017). However, despite ecosystems having quite similar structure, the organization of the species niches may be different; that is, a function performed by a species in an ecosystem can be equivalent within a second similar ecosystem, but in a third ecosystem, its function can be divided among several species, or included as part of the functions of another species (Smith & Smith, 2001). Furthermore, as a result of convergent evolution, some groups of plants and animals worldwide with independent evolutionary histories but under similar environmental conditions, adapt to similar ecological niches, and thus represent ecological equivalents (Whittaker & Levin, 1975; Pianka, 2000).
### Table 4. Examples of sister species of marine fish with wide speciation in the Tropical Eastern Pacific Ocean.

<tbody>
<tr>
<td><em>Sphyrnidae</em></td>
<td><em>Sphyrna zygaena,</em> (Linnaeus, 1758)</td>
<td>Smooth hammerhead</td>
<td>Circumpolar in tropical and temperate seas; California to Mexico, Colombia to Chile.</td>
<td>A coastal-pelagic and semi-oceanic hammerhead often sighted near Surface.</td>
</tr>
<tr>
<td><strong>Carangidae</strong></td>
<td><strong>Decapterus muroadsi</strong> (Temminck &amp; Schlegel, 1844)</td>
<td>Amber-striped scad, Mexican scad</td>
<td>An Indo-Pacific species; southern California to the tip of Baja, Ecuador to Chile, the Revillagigedos and Galapagos.</td>
<td>The Amber-striped scads are a coastal pelagic species found at depths up to 1,050 ft. Adults are pelagic, in oceanic and inshore waters forming schools.</td>
</tr>
<tr>
<td><em>Echinorhinidae</em></td>
<td><em>Echinorhinus cookei,</em> Pietschmann, 1928</td>
<td>Prickly shark</td>
<td>A subtropical to temperate Pacific species; Oregon to Chile.</td>
<td>Demersal, 10-1100 m depth. Reef associated (reef + edges-water column and soft bottom). Soft bottom (mud/sand/gravel/beach)</td>
</tr>
<tr>
<td>Mugilidae</td>
<td><em>Mugil cephalus,</em> Linnaeus, 1758</td>
<td>Striped mullet</td>
<td>This species is widespread throughout the tropics and sub-tropical seas to warm temperate regions.</td>
<td>This species is pelagic near shores, it sometimes forages in lagoons, estuaries and lower courses of rivers and can tolerate freshwater. It is known to breed in its third year of life: adults school in estuaries then move out to sea to spawn in coastal surface water, before returning to estuaries and freshwater (Harrison and Senou 1999). Juveniles feed on zooplankton, larger individuals filter algae, detritus, sediment and small invertebrates.</td>
</tr>
<tr>
<td>Lobotidae</td>
<td><em>Lobotus pacificus,</em> Gilbert, Pacific tripletail 1898</td>
<td></td>
<td>Southern California to the Gulf of California to Perú, Cocos islands.</td>
<td>Occurs in bays and brackish estuaries or sometimes well out to sea around floating objects; juveniles sometimes in flotsam, they may lay on their side at the Surface and mimic a drifting dark leaf.</td>
</tr>
<tr>
<td><strong>Carangidae</strong></td>
<td><strong>Caranx caballus,</strong> Günther, 1868</td>
<td>Green jack</td>
<td>Green jack are widely distributed along the Pacific coast of the Americas, from southern California, USA, to Peru (Mair et al. 2012; Robertson and Allen 2008).</td>
<td>Open water or near escarpments, occasionally moving into more shallow waters to feed. Species associated with floating objects.</td>
</tr>
<tr>
<td><strong>Carangidae</strong></td>
<td><em>Seriola rivoliana,</em> Valenciennes, 1833</td>
<td>Almaco jack</td>
<td>Throughout tropical and subtropical waters, in the eastern Pacific from Oceanside, California to Perú, and Galápagos.</td>
<td>A pelagic schooling species that prefers waters over the continental shelf, and around islands (Smith-Vaniz &amp; Williams, 2015). The depth range for this species is 50 to 300 m (Jiménez Prado &amp; Béarez, 2004).</td>
</tr>
<tr>
<td><strong>Carangidae</strong></td>
<td><em>Uraspis helvola</em> (Forster, 1801)</td>
<td>Whitemouth jack</td>
<td>This species is widely distributed in the Indo-West Pacific but rarely collected. Verified records from the Western Central Pacific area are pending and if <em>U. secunda</em> is a junior synonym, this species is also widely distributed throughout the Atlantic. In the Eastern Central Atlantic, <em>Uraspis helvola</em> occurs off St. Helena and Ascension Islands, and there is also a record from off Cape Verde. In the Indo-West Pacific, this species occurs from off South Africa, Mozambique, Somalia, the Red Sea, off Oman and Bahrain, Sri Lanka, the Andaman Sea, the northern South China Sea, the Hawaiian Islands and offshore islands of the tropical eastern Pacific. Records from the Philippines south to Australia need verification.</td>
<td></td>
</tr>
<tr>
<td><em>Khiosididae</em></td>
<td><em>Kyphosus ocyurus,</em> (Jordan &amp; Gilbert, 1882)</td>
<td>Bluestriped seachub</td>
<td>From southern California to Perú (excluding the bulk of the Gulf of California) and all the oceanic islands. Occasional specimens have also reached Tahiti and Hawai', and there is a resident population in the Marquesas Islands of Polynesia.</td>
<td>Most common around offshore islands, also frequently seen near floating logs far out to sea.</td>
</tr>

</table>

combination of four significant factors stimulated the increase in marine biodiversity. These are (1) an increase in sea level, (2) the formation of biogeographic barriers, (3) an increase in the areas of continental shelves, and (4) an increase in global temperature. Then, between the Cretaceous (~145 mya) and the Tertiary periods, sea level and the temperature dropped, and a mass extinction occurred which extinguished about half of the species of the planet; the recovery took two million years. During the Cenozoic (~66 mya to present), the present temperature gradient from the tropics to the poles was established as well as the consequent global gradient of organic biodiversity.

The first key process that contributed to the increase of biodiversity of the Cenozoic was the formation of biogeographic regions and provinces due to the temperature gradients, promoted by tectonic movements and changing ocean currents. Subsequently, four centers of evolutionary origin (Antarctica, the North Pacific, eastern Indonesia, and the southern Caribbean) are suggested to be the main sources of diversification in the marine environment, increasing biodiversity in other parts of the world (Briggs, 2007). The centers of origin hypothesis (Briggs, 2000; 2006; 2007) assumes that interspecific interactions (competition, predation, etc.) are the main determinants of the number of coexisting species in a habitat, that all available energy is used by the resident species, and that only through finer subdivision of habitat may increase the richness of a community (Pianka, 2000; Ruggiero, 2001; Ruggiero et al., 2015). However, adjustment of the centers of origin hypothesis indicates that species richness at the local scale is increased by processes that occur at the regional scale (Ruggiero, 2001). Thus, typical processes of speciation and migration occurring within biogeographic provinces can add species to these communities without speciation and niche differentiation at the local scale.

The species occupying centers of origin appear to be highly competitive, well adapted, and have the necessary genetic resources to adjust to environmental changes. When species extend their distribution ranges, they can displace less competitive species, and in turn, are exposed to a variety of barriers that can disrupt their genetic integrity (Briggs, 2007). Eventually, the barrier can result in allopatric speciation and ultimately, the generation of new species. Populations of geographical provinces isolated by physical barriers contribute to the overall richness/biodiversity of populations of endemic species produced by allopatric speciation.

The characteristic sympatric speciation within centers of origin and the allopatric speciation of peripheral provinces seem to be the main sources of marine biodiversity. However, Krebs (2003) notes that environmental factors control natural selection in temperate and polar areas, whereas in the tropics, biological competition is more important for evolution. This concept reflects that the core processes for the functioning of ecosystems can be maintained by very few species and questions if there is really a relationship between biodiversity and ecosystem function (Tilman et al., 2014). Finally, although the centers of origin hypothesis (Briggs, 2007) is often supported by certain patterns of species distribution (Mora et al., 2003), it is often not considered valid on multiple grounds by some experts (Morrone, 2002); thus, it is necessary to be taken with caution. In contrast, the species-energy hypothesis (Hillebrand, 2004a) based on a great number of indirect variables such as air temperature, sea temperature, radiation, biomass, productivity, and potential and actual evapotranspiration, which reflect the availability of energy, has been widely accepted in marine environments. However, the major disadvantage of this hypothesis, is that it presents no mechanism that links the energy transfer to biodiversity (Hillebrand, 2004a).

Because increased species richness is a well-established pattern across many taxa and is pervasive in time and space (Willig & Presley, 2017), it is likely that a number of mechanisms are required to generate latitudinal gradients and may be species and habitat dependent; gradients appear not to be based solely on variation in species richness. For example, the evolutionary time hypothesis (Rohde, 1992) that assumes that tropical areas favor high rates of speciation and low rates of extinction because they have a larger geographic area, greater productivity (energy), increased spatial heterogeneity, and a greater geological stability. Furthermore, the area hypothesis predicts that species richness and biodiversity is generally associated with a high susceptibility to allopatric speciation through geographical barrier formation, high probability of covering more niches, and higher total population size (Rosenzweig, 1992; Ruggiero, 2001; Ruggiero et al., 2015).

This hypothesis agrees well with observations of fossil record indicating that tropical areas are centers of evolution, with greater evolutionary speed than mild climate areas (Hillebrand, 2004b). However, the latitudinal gradient in species richness has a few exceptions to the observed spatial pattern. An interesting example (Bolton, 1994) is the green (Chlorophyta), brown (Phaeophyta) and red (Rhodophyta) macrophytic algae that has a tendency to increase towards the poles, attributed to competition for suitable habitats with tropical coral reef species. Another latitudinal gradient related to the distribution range of the species is the “Rapoport’s rule.” This suggests a progressive increase in the size of the geographic ranges of species with latitude, a pattern that is explained as an effect of selection for greater species climate tolerance inhabiting higher latitudes (Stevens, 1989). As species inhabiting temperate-cold regions are adapted to greater climatic variability than tropical species, this allows them to extend their geographical distribution. A similar pattern occurs in marine fish where fishes that live near the ocean surface are distributed in narrow depth ranges, while fishes in deeper areas are distributed over wide ranges (Stevens, 1989; Hughes et al., 2002; Macpherson, 2003; Tittensor et al., 2010; Willig & Presley, 2017).

In parallel, it has been identified that biodiversity also decreases with altitude, aridity, depth, and environmental homogeneity, among other factors. A model based on planktonic foraminifera (Allen et al., 2006) indicated that environmental temperature affects the metabolic speed of individuals and influences in the divergence rate and therefore the tempo of speciation. This indicates that the environmental temperature may be an important controlling factor in speciation rates and, in turn, helps explain the overall decline in species richness with increases in altitude (Briggs, 2007). However, although the temperature is a good indicator of speciation rates, this does not explain why the distribution range can differ in the longitudinal plane. Finally, Allen & Gillooly (2006) reported positive correlations between species richness and speciation rates for some groups of plankton, indicating that the speciation rate varies with species abundance; overall, new species, genera and families evolve under conditions of high biodiversity.

Based on these models and the idea that “biodiversity generates biodiversity,” Briggs (2007) argues that a high rate of speciation developed a high concentration of species in the Indo-Pacific and the southern Caribbean Sea, and that outward migration to warm-temperate
latitudes occurred and from there the migration reaches the poles. One
trophic strategy driving such a pattern in tropical centers of origin, is
herbivory which is a widespread feeding strategy but is rare in tempe-
rate waters. Cold waters are a complicated physiological barrier relative
to the increase in energy demand; thus, Briggs (2006) suggests some
groups have shifted into a type of omnivorous feeding or perform sea-
sonal changes between herbivorous and carnivorous habits. In some
locations, between 57 and 79% of the species depends on their diet of
algae and sea grasses (Kieckbusch et al., 2004).

This suggests that a considerable portion of the tropical marine
biodiversity can be attributed to the presence of species that tend to
evolve by means of ecological specializations, using low energy food
sources. This shift towards an alternative food supply under high com-
petition suggests that sympatric speciation may partially drive evolution
in the tropics. The processes of sympatric speciation (or parapatric)
are suggested to be faster than allopatric processes (Bush & Butlin, 2004),
indicating that the exponential increase in biodiversity during the Ceno-
zoic might be mainly due to the production of centers of origin (Busch &
Butlin, 2004; Mittelbach et al., 2007).

IMPORTANCE OF FUNCTIONAL REDUNDANCY
IN ECOSYSTEM FUNCTION AND THE IMPACT OF
ENVIRONMENTAL DISTURBANCES

Naem et al. (2002) grouped the biodiversity and ecosystem functioning
hypotheses that emerged as mechanisms into three classes according
to how the relationship is modified by removing or adding species that
can include temporarily or trait-based trait redundancy. First, species
are mostly redundant. This premise assumes that systems are sensi-
tive to variation in biodiversity and implies that the loss of species is
compensated by other species or by the incorporation of alien species
that do not add new functions to the system. The basis of this premise
is a classification of species into functional groups formed by redu-
dant species (Walker, 1992). Functional redundancy is based on the
premise that some species perform the same function in communities
and ecosystems, and can, therefore, be replaced with little impact on
ecosystem processes (Walker, 1992; Rosenfeld, 2002).

For the maintenance of ecosystem functions, a minimum number
of species is required in each functional group or ecosystem stability
may become reduced or lost to the extent that the functional groups
disappear (Lawton & Brown 1993); thus, to ensure stable ecosystem
functions, redundancy is required. Second, species are mostly unique
which implies that each species contributes to ecosystem functioning
in a unique way, therefore, species loss or addition causes a noticeable
change in ecosystem function and stability (Naem et al., 1994; Naem
& Li, 1997; Pratchett et al., 2011).

Keystone species or ecosystem engineering species are often cited
as examples of unique species. Engineer species modify the available
resources for the other members of the community through the modi-
fication of the habitat (e.g., oysters or beaver dam builders; Lawton,
1994). These species have a disproportionate functional impact (posi-
tive or negative depending on the processes under study) on community
or ecosystem abundance and biodiversity (Scherer-Lorenzen, 2005).
Third, the impacts of species are context-dependent and therefore
idiosyncratic or unpredictable (Fariña et al., 2003). The idiosyncratic
response hypothesis (Lawton, 1994) argues that the impact based on
the loss or addition of a species in an ecosystem can be insignificant or
highly significant, depending on environmental conditions (e.g., fertility,
food availability, disturbance regime, etc.), the nature of the added or
loss species, and the nature of the species with which it interacts.

To illustrate how the functional redundancy of species in a com-
munity depends on the environmental context (premise three above),
Wells & Poff (2001) developed a theoretical scenario based on a
hypothetical feeding guild formed by three lotic species (A, B and C).
These three species belong to a guild of grazers and current velocity
is vital to their permanence. These species are potentially redundant at
low velocities since they feed on algae and associated organisms and
detritus, with overlap in their fundamental niche. On average, all three
species have the same effect on the rate at which algae are removed
from the substrate. However, the relative importance of each species
in this process changes dramatically as velocity increases with their
functions being similar under low speed conditions, but not redundant
at intermediate and high current velocities. Thus, if we conclude that
the three species are redundant based on their functional contributions
in the low velocity or the average value of the three gradients, and then
we remove species C, the community would lose an important func-
tional component in the system. Unfortunately, there are a limited number
of studies that address this type of issue that provides an unlimited
overview of the functions of the species, and thus may give a false
diagnosis of redundancy.

Studies that do address such changes or impacts indicate variable
results depending on duration/frequency of disturbances and these are
scale-dependent (local, regional). For example, Bellwood et al. (2006)
conducted an experimental study in the Great Barrier Reef, simulating
changes from a macroalgae-dominated to a coral- and epilithic-do-
minated state, inducing the reversal of the dominance of macroalgae
through functional herbivorous fishes. Surprisingly, the reversal through
direct removal of macroalgae was not the result of grazing parrotfish
(Scaridae) and surgeonfish (Acanthuridae), the most common herbivo-
rous reef fish, or any of the other 43 herbivores species in the area, but
primarily from a single species, the batfish Platax pinnatus (Linnaeus,
1758) (Ephippidae, that was previously listed as zoobentivore). The spe-
cies was observed consistently ingesting large pieces of Sargassum
(the dominant macroalgae) and algae. The batfish is relatively rare in
the Great Barrier Reef (1.6 individual/ha), but it has the ability to remove
12,750 kg/yr; however, the importance of removing macroalgae by this
species was unknown.

This species, according to Bellwood et al. (2006), represents a
‘sleeping’ functional group-species or group of species able to perform
a particular function role but only under certain exceptional circumstan-
ces. This case highlights the importance of identifying and protecting
these species or species groups that support resilience and regenera-
tion of complex ecosystems. Similarly, the green humphhead parrotfish,
Bolbometopon muricatum (Valenciennes, 1840), from the Indo-Pacific,
was primarily responsible for bioturbation of coral reefs, each fish con-
sumes about five tons of carbonate coral reef per year, corresponding
to about half of the live coral (Bellwood et al., 2003, Bellwood & Choat,
2011). Overfishing of this species has changed the dynamics of accre-
tion of reefs (Bellwood et al., 2003; Bellwood & Choat, 2011).

Coral reef ecosystems are increasingly subject to severe, lar-
ge-scale disturbances caused by climate change (e.g., coral bleaching)
and other more direct anthropogenic impacts causing coral loss; the-
se cause changes in habitat structure, which has additional effects on abundance and biodiversity of coral reef fishes (Wilson et al., 2006). Declines in the biodiversity and abundance of coral reef fishes are of considerable concern, given the subsequent loss of ecosystem function (reviewed in Pratchett et al., 2008). Pratchett et al. (2011) reviewed the effects of coral loss throughout the world on the biodiversity of fishes and also on individual functional responses of fishes. Extensive (> 60%) coral loss led to declines in fish biodiversity; most fishes declined in abundance following disturbances that caused > 10% declines in local coral cover. Response biodiversity, which is considered critical in maintaining ecosystem function and promoting resilience, was very low for corallivores, but was much higher for herbivores, omnivores and carnivores. They indicated that sustained climate change poses a significant threat to coral reef ecosystems and biodiversity hotspots are no less susceptible to projected changes in biodiversity and function (Pratchett et al., 2011). Although there is no global agreement on the effects of species loss on ecosystem functioning, it has been noted that deforestation, introduction of exotic species, habitat destruction, isolation or fragmentation of habitats and pollution can contribute to local, regional and global extinction of species causing an inevitable ecosystem degradation and loss of services to society (Sodhi et al., 2009).

However, Cheal et al. (2008) suggested that coral reef fish biodiversity may not be a reliable indicator of reef resilience but predicted declines in coral cover due to global warming are likely to cause changes in the observed structure of reef fish communities; the nature of these changes and associated functional capacity to assist ecosystem recovery will vary among reefs because of differences in functional diversity. Finally, Denis et al. (2017) based on the 1983 severe coral reef bleaching data off Tikus Island Indonesia, found clear signs of coral assemblage complexity recovery approaching pre-El Niño conditions five years after the event. They also noted that, independent of the changes in species richness, this return in structural complexity was accompanied by a global decrease in species number associated with functional redundancy (each morphological entity) and an increase in the functional vulnerability (number of unique single-species:functional groups). They suggested an overall functional erosion of the coral assemblage and indicated that the role of the coral reef habitat could be strongly imperiled under repeated or synergistic disturbances.

Currently, there has been a surge of studies examining the relationship between phylogenetic (species) biodiversity, functional diversity, and ecosystem sustainability (e.g., Cowman, 2014; Floeter et al., 2018) using different approaches and relative to a better understanding of anthropogenic-induced impacts on sustainability. Although there are multiple definitions (Naeem & Li, 1997; Tilman, 2001; Diaz et al., 2007; Martín-López et al., 2007; Cadotte et al., 2013; Winemiller et al., 2015), all agree on the importance of evaluating the functional role of species within an ecosystem. The approaches vary but most are through multidisciplinary and multivariate studies (Schulze & Mooney, 1994; Winemiller et al., 2015; Pianka et al., 2017; Floeter et al., 2018) where functional groups are defined according to the concept that species with high overlap of information on ecological and morphological traits are placed together and thus play similar ecological roles (Alvarez-Filip & Reyes-Bonilla, 2006; Cadotte et al., 2013; Winemiller et al., 2015; Pianka et al., 2017).

Each group is characterized by its own unique combination of functional features and outcomes provide a manageable number of groups that maximize the biological coherence of its members (Field et al., 1982; Simberloff & Dayan, 1991; Petchey & Gaston, 2002; Winemiller et al., 2015). Recently, Floeter et al. (2018) documented that functional traits and the environment influence phylogenetic lineages, such that acquiring a functional trait may drive evolution of other traits or behaviors and that an improvement of our understanding of mechanisms of species assemblages are enhanced using both metrics in coral reef fish communities.

In theory, the presence of multiple dominant or subordinate species increases the functional redundancy within each functional group and provides ecosystem resilience to respond or adapt to disturbances (Giller & O’Donovan, 2002). Further, functional redundancy also reduces the likelihood of invasion of exotic species (Naeem et al., 1994; Walker et al., 1999; Steneck, 2001; Rosenfeld, 2002; Hooper et al., 2005). The greater the number of functionally similar species, each with different responses to environmental constraints, the greater the likelihood that at least one species survives against possible disturbances (Walker, 1992, 1995; Naeem, 1998; Diaz et al., 2013).

For example, let us assume that an ecosystem is facing a drought, then a fire, and then is on flood. According to the functional diversity hypothesis, the ecosystem will have species that can tolerate drought, some that are fire-tolerant, and some that are resistant to flooding. If true, then two scenarios are likely: 1) the ecosystem may show resistance, remaining unchanged because species richness moderates the damage; or 2) the ecosystem may show resilience, quickly returning to its original state because tolerant species contribute to recovery and compensate for the functional loss of other species who showed less resistance (Naeem, 2002).

After removing a species within a fully formed group, reduced redundancy makes the remaining species increase their density to offset the functional contribution of the lost species. For example, in algae when a compensating effect between species of the same functional group is observed; biomass remains relatively constant despite fluctuations in species abundance (Steneck, 2001). Functional redundancy is good because it increases ecosystem resilience (Walker, 1992; Cheal et al., 2008) and important functional groups comprised of a few or a single species deserve attention regarding conservation priority because their functions may be rapidly lost (Walker, 1992).

CONCLUSIONS

The analysis of functional diversity is a powerful and complementary tool to the classic indices of biological biodiversity (richness, dominance, equity, etc.) and taxonomic biodiversity indices (taxonomic biodiversity, taxonomic differentiation, average taxonomic differentiation, variation in taxonomic distinction). Biodiversity indicates richness and proportions, taxonomic biodiversity reflects the structure and phylogenetic variability, and functional diversity suggests the role of species in the ecosystem. Moreover, functional diversity studies can be used as a tool to predict the functional consequences of invasions or invasion front speciation events (Chuang & Peterson, 2016) and biotic changes caused by humans like overfishing, habitat loss, and climate change (Heenan & Williams, 2013; Villéger et al., 2017). The functional diversity approach offers an opportunity for a better understanding of coral reef ecosystem responses, and the associated fish communities, to natural and anthropogenic disturbances.
Review fish functional diversity

ACKNOWLEDGEMENTS

The authors are grateful for the economic support provided by CONACyT (project 205024) and SEP-CONACyT (project 241486). WHCE, LAAC, and XGMS were supported by programs at the Instituto Politécnico Nacional: Estímulo al Desempeño de los Investigadores (EDI) and Comisión de Operación y Fomento de Actividades Académicas (COFAA). Thanks to Armando Hernandez Lopez who develop Figure 1. In loving memory of Devis Samuel Palacios Salgado an excellent student, researcher, colleague and friend, rest in peace.
